# Joins

Correlating Tables with Foreign Keys

# Last Lecture

- Recall in the last lecture we learned about sub-queries
- Sub-queries could be used to answer questions like *“Give me the name of all tracks on the album named ‘Machine Head’”*

```
SELECT name  
FROM tracks  
JOIN albums ON tracks.AlbumId = albums.AlbumId  
WHERE albums.Title = "Machine Head"
```

# Joins

- While Sub-Queries are useful and used in production environments, this is a common operation that is typically and more efficiently achieved with JOINS

```
SELECT name  
FROM tracks  
JOIN albums ON tracks.AlbumId = albums.AlbumId  
WHERE albums.Title = "Machine Head"
```

# Joins

- The basic join syntax is

```
SELECT <cols>  
FROM <table name>  
JOIN <table name> ON  
<condition>  
WHERE <predicates>
```

```
SELECT name  
FROM tracks  
JOIN albums ON tracks.AlbumId = albums.AlbumId  
WHERE albums.Title = "Machine Head"
```

# Joins

- This example shows what is called an *Inner Join*
- An inner join returns all rows for which the condition in the join clause is true

```
SELECT name  
FROM tracks  
JOIN albums ON tracks.AlbumId = albums.AlbumId  
WHERE albums.Title = "Machine Head"
```

# Joins

- Can also be written out explicitly with an INNER keyword
- Inner joins are the most common sort of join you will work with

```
SELECT name
FROM tracks
INNER JOIN albums ON tracks.AlbumId = albums.AlbumId
WHERE albums.Title = "Machine Head"
```

# Joins

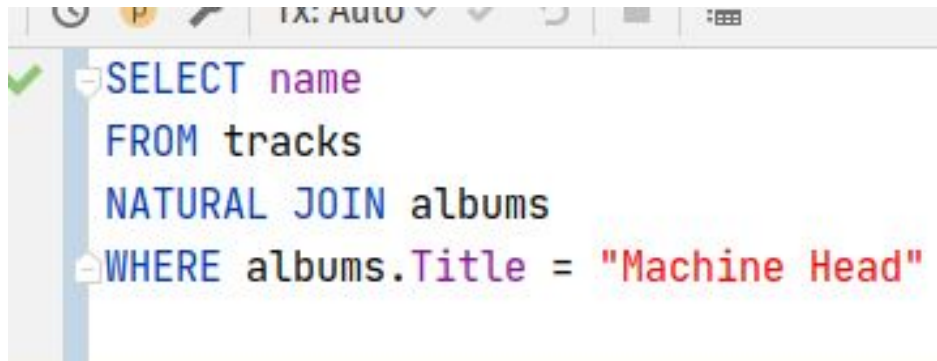

- Note that the join condition uses the Foreign Key in tracks and the key in albums
- The join condition is usually an equality condition, but it doesn't have to be

```
SELECT name
FROM tracks
INNER JOIN albums ON tracks.AlbumId = albums.AlbumId
WHERE albums.Title = "Machine Head"
```

# Natural Joins

- It is often the case that the columns in one table line up with the columns on another table
- FKs typically have the same name as the referred table
- If this is the case, you can use a natural join and omit the equality expression

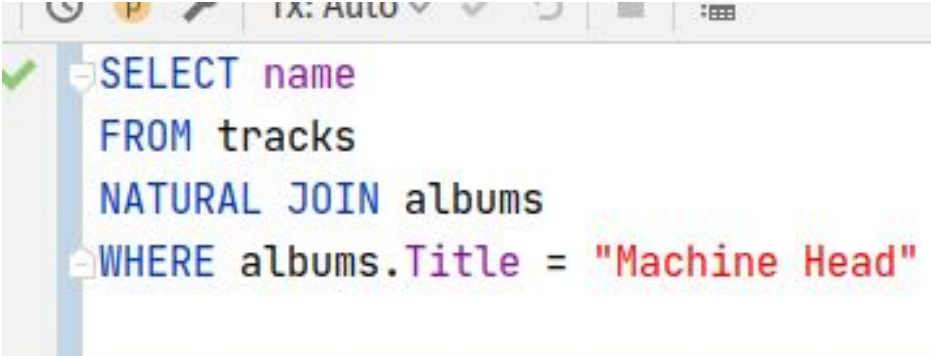

A screenshot of a SQL query in a code editor. The query is: 

```
SELECT name
FROM tracks
NATURAL JOIN albums
WHERE albums.Title = "Machine Head"
```

 The code is color-coded: 'SELECT' is blue, 'name' is purple, 'FROM' is blue, 'tracks' is black, 'NATURAL JOIN' is blue, 'albums' is black, 'WHERE' is blue, 'albums.Title' is purple, '=' is black, and '"Machine Head"' is red. A green checkmark icon is visible on the left side of the code editor.

# Natural Joins

- A little cleaner
- Rare in practice
  - Why?

A screenshot of a SQL query in a code editor. The query is: `SELECT name  
FROM tracks  
NATURAL JOIN albums  
WHERE albums.Title = "Machine Head"`. The code is color-coded: `SELECT` is blue, `name` is purple, `FROM` is blue, `tracks` is blue, `NATURAL JOIN` is blue, `albums` is blue, `WHERE` is blue, `albums.Title` is purple, `=` is blue, and `"Machine Head"` is red. A green checkmark icon is visible on the left side of the first line.

# Outer Join

- Inner joins are fairly intuitive
- But sometimes you want ALL the rows of a table, even if there isn't a match in the joined table
- To accomplish this we need to use OUTER JOINS

```
SELECT artists.name, albums.Title  
FROM artists  
LEFT OUTER JOIN albums  
ON artists.ArtistId = albums.ArtistId
```

# Outer Join

- Note that I am selecting values from both the artists as well as the albums table
- This query will return all artist/album combinations *as well as artists who have no albums, with the album value set to null*

```
SELECT artists.name, albums.Title  
FROM artists  
LEFT OUTER JOIN albums  
ON artists.ArtistId = albums.ArtistId
```

# Outer Join

- If I changed this to an inner join, artists who had no albums would be excluded from the results

```
SELECT artists.name, albums.Title  
FROM artists  
LEFT OUTER JOIN albums  
ON artists.ArtistId = albums.ArtistId
```

# Outer Join

- We could change this to a RIGHT OUTER JOIN to include nulls from the right table (in this case albums)
- The artists table is considered “left” of the albums table
- Hence LEFT OUTER JOIN

```
SELECT artists.name, albums.Title  
FROM artists  
RIGHT OUTER JOIN albums  
ON artists.ArtistId = albums.ArtistId
```

---

# Outer Join

- And, finally, we could use a FULL OUTER JOIN to include null values from both tables

```
SELECT artists.name, albums.Title
FROM artists
FULL OUTER JOIN albums
    ON artists.ArtistId = albums.ArtistId
```

# Outer Join

- As you might have noticed, SQLite does not support Right Outer Joins or Full Outer Joins
- In practice, Outer Joins are rare, and Right and Full outer joins are even rarer

```
SELECT artists.name, albums.Title
FROM artists
FULL OUTER JOIN albums
ON artists.ArtistId = albums.ArtistId
```

The image shows a snippet of SQL code in a text editor. The code is a SELECT statement that joins the 'artists' and 'albums' tables using a FULL OUTER JOIN. The 'artists' table has a column 'name' and the 'albums' table has a column 'Title'. The join is based on the 'ArtistId' column in both tables. The code is color-coded: 'SELECT' is blue, 'artists.name' is purple, 'albums.Title' is red, 'FROM' is blue, 'artists' is black, 'FULL OUTER JOIN' is blue, 'albums' is black, and 'ON artists.ArtistId = albums.ArtistId' is black. There is a lightbulb icon above the code and a green checkmark icon to the left of the first line.

# Self Joins

- Chinook DB has a self-referential table in it
- Employees have a reference to their boss via the ReportTo foreign key
- How do we deal with that?

```
SELECT artists.name, albums.Title
FROM artists
FULL OUTER JOIN albums
ON artists.ArtistId = albums.ArtistId
```

# Self Joins

- It's pretty much the same technique using a JOIN
- However, you need to *alias* the table to a new name
- And you need to disambiguate the column names
- Both of these use the “as” syntax

```
SELECT employees.FirstName as FirstName,  
       employees.EmployeeId as EmployeeId,  
       bosses.FirstName as BossFirstName,  
       bosses.EmployeeId as BossEmployeeId  
FROM employees  
JOIN employees AS bosses  
WHERE employees.ReportsTo = bosses.EmployeeId
```

---

# Joins As Venn Diagrams

- One way to think about the types of joins is to use a ven diagram
- Inner Joins are the *intersection* of the two relational sets

The following diagram illustrates the **INNER JOIN** clause:

---

# Joins As Venn Diagrams

- Left Joins are all the left table and whatever matches in the right table

The following Venn Diagram illustrates the **LEFT JOIN** clause.

---

# Joins As Venn Diagrams

- And Full Outer Joins include all rows from all tables
- I personally find it easier to just think in terms of nulls in the join condition:
  - Inner - ignore nulls
  - Outer - keep nulls

---

# More Exotic Joins

- There are some more exotic joins, such as the cross join
- This creates all possible combinations of album rows and artist rows
- I have never used it, but I can imagine uses for it

```
SELECT *  
FROM albums  
CROSS JOIN artists
```

---

# Joining Multiple Tables

- Sometimes you need to join across multiple tables to get what you want

*“Give me the name of all tracks by AC/DC”*

```
SELECT
    tracks.name
FROM
    tracks
JOIN albums
    ON tracks.AlbumId = albums.AlbumId
JOIN artists
    ON albums.ArtistId = artists.ArtistId
WHERE artists.name = "AC/DC";
```

---

# Joining Multiple Tables

- Column naming can get tricky when you are joining multiple table
- You may have to use aliasing to get exactly what you want

```
SELECT
    tracks.name
FROM
    tracks
JOIN albums
    ON tracks.AlbumId = albums.AlbumId
JOIN artists
    ON albums.ArtistId = artists.ArtistId
WHERE artists.name = "AC/DC";
```

---

# Joins Summary

- Joins are a way to correlate data across tables
- There are a few different types of joins
  - Inner joins are the most common
- A table with an FK to itself can be joined by *aliasing* the table in the join clause
- You can disambiguate table and column names using the AS keyword
- Joining across multiple tables involves multiple JOIN clauses
